2016 ESC Position Paper on cancer treatments and cardiovascular toxicity developed under the auspices of the ESC Committee for Practice Guidelines

The Task Force for cancer treatments and cardiovascular toxicity of the European Society of Cardiology (ESC)

Authors/Task Force Members: Jose Luis Zamorano* (Chairperson) (Spain), Patrizio Lancellotti* (Co-Chairperson) (Belgium), Daniel Rodriguez Muñoz (Spain), Victor Aboyans (France), Riccardo Asteggianno (Italy), Maurizio Galderisi (Italy), Gilbert Habib (France), Daniel J. Lenihan1 (USA), Gregory Y. H. Lip (UK), Alexander R. Lyon (UK), Teresa Lopez Fernandez (Spain), Dania Mohty (France), Massimo F. Piepoli (Italy), Juan Tamargo (Spain), Adam Torbicki (Poland), and Thomas M. Suter (Switzerland)

ESC Committee for Practice Guidelines (CPG): Jose Luis Zamorano (Chairperson) (Spain), Victor Aboyans (France), Stephan Achenbach (Germany), Stefan Agewall (Norway), Lina Badimon (Spain), Gonzalo Barón-Esquivias (Spain), Helmut Baumgartner (Germany), Jeroen J. Bax (The Netherlands), Héctor Bueno (Spain), Scipione Carerj (Italy), Veronica Dean (France), Çetin Erol (Turkey), Donna Fitzsimons (UK), Oliver Gaemperli (Switzerland), Paulus Kirchhof (UK/Germany), Philippe Kohl (Belgium), Patrizio Lancellotti (Belgium), Gregory Y. H. Lip (UK), Petros Nihoyannopoulos (UK), Massimo F. Piepoli (Italy), Piotr Ponikowski (Poland), Marco Roffi (Switzerland), Adam Torbicki (Poland), António Vaz Carneiro (Portugal), and Stephan Windecker (Switzerland)

Document Reviewers: Stephan Achenbach (CPG Review Coordinator) (Germany), Giorgio Minotti (CPG Review Coordinator) (Italy), Stefan Agewall (Norway), Lina Badimon (Spain), Héctor Bueno (Spain), Daniela Cardinale (Italy), Scipione Carerj (Italy), Giuseppe Curigliano (Italy), Evandro de Azambuja (Belgium), Susan Dent (Canada), Çetin Erol (Turkey), Michael S. Ewer (USA), Dimitrios Farmakis (Greece), Rainer Fietkau (Germany), Donna Fitzsimons (UK), Oliver Gaemperli (Switzerland), Paulus Kirchhof (Germany/UK), Philippe Kohl (Belgium), Paul McGale (UK), Piotr Ponikowski (Poland), Juergen Ringwald (Germany), Marco Roffi (Switzerland).

Preamble

Guidelines and position papers written under the auspices of the ESC Committee for Practice Guidelines (CPG) summarize and evaluate all available evidence on a particular issue at the time of the writing process, with the aim of assisting health professionals in selecting the best management strategies for an individual patient with a given condition, taking into account the impact on outcome, as well as the risk–benefit ratio of particular diagnostic or therapeutic means. CPG Guidelines and position papers should help health professionals to make decisions in their daily practice. However, the final decisions concerning an individual patient must be made by the responsible health professionals in consultation with the patient and caregiver as appropriate.

Members of this Task Force were selected by the ESC to represent professionals involved with the medical care of patients with this pathology. Selected experts in the field undertook a comprehensive review of the published evidence for management (including diagnosis, treatment, prevention and rehabilitation) of a given condition according to CPG policy. A critical evaluation of diagnostic and therapeutic procedures was performed, including assessment of the risk–benefit ratio. Estimates of expected health outcomes for larger populations were included, where data exist.

The experts of the writing and reviewing panels provided declarations of interest forms for all relationships that might be perceived as real or potential sources of conflicts of interest. These forms were compiled into one file and can be found on the ESC website (http://www.escardio.org/guidelines). Any changes in declarations of
interest that arise during the writing period must be notified to the ESC and updated. The Task Force received its entire financial support from the ESC without any involvement from the healthcare industry.

The ESC CPG supervises and coordinates the preparation of new guidelines and position papers produced by task forces, expert groups or consensus panels. The Committee is also responsible for the endorsement process of these documents. The CPG documents undergo extensive review by the CPG and external experts. After appropriate revisions, these documents are approved by all the experts involved in the Task Force. The finalized document is approved by the CPG for publication in the European Heart Journal. The CPG documents were developed after careful consideration of the scientific and medical knowledge and the evidence available at the time of their dating.

The task of developing CPG documents covers not only integration of the most recent research, but also the creation of educational tools and implementation programmes for the recommendations. To implement these documents, condensed pocket guidelines versions, summary slides and an electronic version for digital applications (smartphones, etc.) are produced as well as other educational tools depending on the topic. These versions are abridged and thus, if needed, one should always refer to the full text version, which is freely available on the ESC website. The National Cardiac Societies of the ESC are encouraged to endorse, translate and implement all CPG documents (guidelines and position papers). Implementation programmes are needed because it has been shown that the outcome of disease may be favourably influenced by the thorough application of clinical recommendations.

Surveys and registries are needed to verify that real-life daily practice is in keeping with what is recommended in the guidelines, thus completing the loop between clinical research, writing of guidelines, disseminating them and implementing them into clinical practice.

Health professionals are encouraged to take the CPG Guidelines and Position Papers fully into account when exercising their clinical judgment, as well as in the determination and the implementation of preventive, diagnostic or therapeutic medical strategies. However, these CPG documents do not override in any way whatsoever the individual responsibility of health professionals to make appropriate and accurate decisions in consideration of each patient’s health condition and in consultation with that patient and the patient’s caregiver where appropriate and/or necessary. It is also the health professional’s responsibility to verify the rules and regulations applicable to drugs and devices at the time of prescription.

1. Introduction

Advances in treatment have led to improved survival of patients with cancer, but have also increased morbidity and mortality due to treatment side effects. Cardiovascular diseases (CVDs) are one of the most frequent of these side effects, and there is a growing concern that they may lead to premature morbidity and death among cancer survivors. This may be the result of cardiotoxicity, which involves direct effects of the cancer treatment on heart function and structure, or may be due to accelerated development of CVD, especially in the presence of traditional cardiovascular risk factors. Although the field of cardio-oncology has received increasing attention in recent years, many aspects of both radiation-induced and cancer drug–induced CVD are still to be fully elucidated. Furthermore, the inability to predict the long-term consequences of cancer treatment–associated cardiovascular side effects leads to under- or overdiagnosis of CVD, sometimes resulting in the failure to prevent adverse events and sometimes to inappropriate interruption of a potentially lifesaving cancer treatment.

The complex issue of CVD as a consequence of previous cancer treatment requires the creation of multidisciplinary teams involving specialists in cardiology, oncology and other related fields. The mutual interest to provide optimal care for patients with cancer and cancer survivors is an important motivation for the development of cardio-oncology teams. However, the extent of care and the interaction between the disciplines involved has not yet been defined. The complexity of the clinical questions to be addressed by cardio-oncologists will require the definition of a curriculum describing the necessary knowledge and skills to deliver optimal care and the hospital setting in which these experts will be active. These cardio-oncology teams should also be involved in the long-term surveillance of cancer survivors with a potential for late-onset cardiovascular complications and in the development of potential new treatments that may have cardiotoxic effects, as well as in the evaluation of cardiac events related to such drugs.

This document reviews the different steps in cardiovascular monitoring and decision-making before, during and after cancer treatment with potential cardiovascular side effects. Although this document is not a formal clinical practice guideline, it aims to assist professionals involved in the treatment of patients with cancer and survivors by providing an expert consensus regarding current standards of care for these individuals.

In general, the cardiovascular complications of cancer therapy can be divided into nine main categories, which are discussed in this document:

- myocardial dysfunction and heart failure (HF);
- coronary artery disease (CAD);
- valvular disease;
- arrhythmias, especially those induced by QT-prolonging drugs;
- arterial hypertension;
- thromboembolic disease;
- peripheral vascular disease and stroke;
- pulmonary hypertension and
- pericardial complications.

2. Cardiovascular complications of cancer therapy: pathophysiology and management

2.1 Myocardial dysfunction and heart failure

2.1.1 Pathophysiology and clinical presentation

Myocardial dysfunction and HF, frequently described as cardiotoxicity, are the most concerning cardiovascular complications of cancer therapies and cause an increase in morbidity and mortality. A collaborative effort among specialists involved in the treatment of patients...
with cancer is critical to prevent and manage cardiotoxicity while not compromising cancer care, to maximize the patient’s overall outcome. The time point when cardiotoxicity becomes clinically manifest varies substantially; some cancer treatments induce side effects that appear early after exposure—and therefore may adversely affect oncological therapy—while others generate cardiac injuries resulting in clinical problems only years later. In addition, some cancer drugs, for example, anthracyclines, can induce progressive cardiac remodelling as a late consequence of earlier myocyte damage, resulting in late cardiomyopathy, while others may cause transient cardiac dysfunction without long-term consequences.

The prediction of long-term cardiovascular prognosis is frequently challenging because patients with cancer typically receive multiple cancer drugs and sometimes radiation, with the potential for cardiotoxic effects from interactions among the different therapeutic modalities.

Left ventricular (LV) dysfunction and HF are relatively common and serious side effects of cancer treatment. Survivors of paediatric cancer, treated with anthracyclines and/or mediastinal radiotherapy, have a 15-fold increased lifetime risk for HF compared with matched controls. In older patients with pre-existing cardiovascular risk, the short-term risk for developing HF is also increased. For example, survivors of aggressive non-Hodgkin lymphoma have a 17% incidence of clinical HF at 5 years. There is also growing awareness of the occurrence of LV dysfunction or HF caused by tyrosine kinase inhibitors (TKIs), particularly in cancer patients with pre-existing cardiovascular risk factors. Table 1 provides an overview of the incidence of LV dysfunction with different chemo-therapeutic drugs.

### 2.1.1.1 Anthracyclines

Anthracyclines have high efficacy for treatment of solid tumours and haematological malignancies, and avoiding their use due to concerns about cardiac side effects may negatively impact prognosis. On the other hand, anthracyclines may cause irreversible cardiac damage, which in turn affects prognosis. For example, doxorubicin is associated with a 5% incidence of congestive HF when a cumulative lifetime dose of 400 mg/m² is reached, and higher doses lead to an exponential increase in risk, up to 48% at 700 mg/m². However, there is considerable variability among patients in their susceptibility to anthracyclines. While many tolerate standard-dose anthracyclines without long-term complications, treatment-related cardiac toxicity may occur as early as after the first dose in other patients.

The most commonly accepted pathophysiological mechanism of anthracycline-induced cardiotoxicity is the oxidative stress hypothesis, which suggests that the generation of reactive oxygen species and lipid peroxidation of the cell membrane damage cardiomyocytes. Other mechanisms have been suggested to play a role. For a detailed discussion of the cellular and molecular mechanisms, the reader is referred to two reviews.

The cardiotoxicity of anthracyclines may be acute, early or late. Acute toxicity, predominantly supraventricular arrhythmia, transient LV dysfunction and electrocardiographic (ECG) changes, develops in <1% of patients immediately after infusion and is usually reversible. However, acute cardiac dysfunction may also reflect myocyte injury that eventually can evolve into early or late cardiotoxicity. There are no proven strategies to identify if cardiac dysfunction is reversible or progressive; however, elevation of cardiac biomarkers may be a way to identify patients at risk for long-term cardiotoxicity.

Early effects occur within the first year of treatment, while late effects manifest themselves after several years (median of 7 years after treatment). In patients treated with commonly used anthracycline doses and >65 years of age, the rate of anthracycline-associated HF

*When used in combination with anthracyclines and cyclophosphamide.

*In patients receiving concurrent anthracyclines.
can be as high as 10%.

This classification (early and late) is based on retrospective studies in which the LV ejection fraction (LVEF) decline was determined either after HF development or on random evaluations in paediatric patients with cancer. A recent study by Cardinale et al., involving 2625 patients (mean follow-up 5.2 years), showed a 9% overall incidence of cardiotoxicity after anthracycline treatment, and 98% of cases occurred within the first year and were asymptomatic. Anthracycline-induced cardiotoxicity is most likely a phenomenon characterized by continuous progressive decline in LVEF. Many affected patients may initially be asymptomatic, with clinical manifestations appearing years later, often in the context of other triggering factors, which may indicate that anthracyclines negatively affect compensatory mechanisms.

Furthermore, if anthracycline-associated cardiac dysfunction is detected early and treated with HF medications, patients frequently have a good functional recovery. Conversely, if patients are identified late after the onset of cardiac dysfunction, HF is typically difficult to treat. Risk factors for anthracycline-related cardiotoxicity include lifetime cumulative dose, infusion regimen and any condition that increases cardiac susceptibility, including pre-existing cardiac disease, hypertension, concomitant use of other chemotherapies or mediastinal radiation therapy and older age (>65 years).

The developing heart is also particularly vulnerable, and paediatric patients treated with anthracyclines are at an exceedingly high risk for anthracycline cardiotoxicity (Table 2). In patients with one or multiple risk factors for anthracycline cardiotoxicity, the cumulative dose vs. cardiotoxicity curve is shifted to the left and these patients should be monitored carefully or alternative chemotherapeutics considered.

Anthracyclines (daunorubicin, doxorubicin, epirubicin, idarubicin) or anthraccenedione (mitoxantrone).
over time in cardiotoxicity was not seen in the trials of trastuzumab as adjuvant therapy in breast cancer; indeed, a low risk for new-onset cardiotoxicity after completion of trastuzumab therapy was found.\textsuperscript{48–51} Long-term follow-up (up to 10 years) data are reassuring in terms of the absence of late-onset HF in patients with low baseline cardiovascular risk treated with trastuzumab.\textsuperscript{48–51} In contrast to anthracyclines, trastuzumab cardiotoxicity typically manifests during treatment. This has led to the implementation of different cardiotoxicity surveillance protocols that vary across countries and centres. Generally, trastuzumab-associated cardiotoxicity is not believed to be cumulative-dose related, although twice the rate of LV dysfunction was reported when patients were treated for 24 rather than the usual 12 months.\textsuperscript{49} Trastuzumab-induced LV dysfunction and HF are usually reversible with trastuzumab interruption and/or treatment with HF therapies.\textsuperscript{52} The mechanism of anti-HER2 drug-induced cardiotoxicity includes structural and functional changes in contractile proteins and mitochondria, but it rarely leads to cell death, explaining the potential for reversibility.\textsuperscript{53,54} Risk factors for anti-HER2 drug-induced cardiotoxicity include previous exposure to anthracyclines, short time (3 weeks vs. 3 months) between anthracycline and anti-HER2 treatment, pre-existing arterial hypertension, low LVEF and older age.\textsuperscript{3,55} One of the most relevant clinical implications of trastuzumab-induced cardiotoxicity is treatment interruption, which is associated with an increase in cancer recurrence.\textsuperscript{56} In patients with HER2-positive breast cancer receiving adjuvant trastuzumab, cardiotoxicity was the most common reason for treatment interruption in 13.5% of patients (30% for HF and 70% for asymptomatic LVEF decline). In most trastuzumab breast cancer registration trials, treatment was stopped when patients developed HF or (in asymptomatic patients) when LVEF dropped below 45%.\textsuperscript{52} There are no randomized trials to prove that HF drugs will improve cardiac function in patients with trastuzumab-associated cardiac dysfunction. However, analogous to the experience in patients with anthracycline cardiotoxicity, trastuzumab-associated cardiac dysfunction is likely to improve when these patients are treated with angiotensin-converting enzyme (ACE) inhibitors.\textsuperscript{56,58} The cardiotoxicity risk of other anti-HER2-targeted therapies (laptatinib, pertuzumab and T-DM1) appears similar to that of trastuzumab. In a large trial of breast cancer patients comparing the efficacy of adjuvant trastuzumab alone vs. trastuzumab and adjuvant laptatinib in >8000 women with a median follow-up of 4.5 years, the incidence of cardiotoxicity ranged from 2 to 5%, and 2 to 3% of women experienced HF.\textsuperscript{57} In this trial, where cardiac function was assessed prospectively and compared with that at baseline, modern schemes of adjuvant or neoadjuvant chemotherapy were used, including anthracyclines in >70% of patients. The cardiotoxicity risk for T-DM1 and pertuzumab also appear similar to trastuzumab, although prospective data from large adjuvant trials are not yet available.\textsuperscript{58,59}

2.1.1.4 Inhibition of the vascular endothelial growth factor signalling pathway

Inhibition of the vascular endothelial growth factor (VEGF) signalling pathway benefits patients diagnosed with one of several different solid cancers, but some of the VEGF inhibitors can cause reversible or irreversible cardiac side effects, particularly when used with or after conventional chemotherapies. In a large trial of patients with breast cancer, where cardiac function was prospectively assessed, the anti-VEGF antibody bevacizumab used after chemotherapy induced LV dysfunction in 2% of patients and HF (NYHA III or IV) in 1% of patients.\textsuperscript{60} Similarly, cardiotoxicity was found for the TKIs sunitinib, pazopanib and axitinib. These drugs induce cardiac dysfunction in 3–15% of patients and symptomatic HF in 1–10% of patients.\textsuperscript{51–64} Other anti-VEGF inhibitors such as sorafenib and vandetanib also induce cardiac dysfunction, but prospective data from large clinical trials are missing. A recent meta-analysis evaluated the risk of congestive HF associated with all US Food and Drug Administration–approved VEGF receptor TKIs. A total of 10 647 patients from 21 randomized phase II and III trials using approved VEGF receptor TKIs (sunitinib, sorafenib, pazopanib, axitinib, vandetanib, cabozantinib, ponatinib and regorafenib) were included. A significant 2.69-fold increase in the risk of all grades of congestive HF was observed with VEGF receptor TKIs compared with controls not receiving TKIs. However, the risk of severe HF was not significantly increased. The risk of relatively specific TKIs (axitinib) was similar to relatively non-specific TKIs (sunitinib, sorafenib, vandetanib and pazopanib).\textsuperscript{65}

VEGF inhibitors also cause substantial arterial hypertension, potentially affecting cardiac function.\textsuperscript{66} Many anti-VEGF cancer drugs inhibit multiple signalling pathways, and identification of the pathophysiological mechanism causing cardiotoxicity can be challenging (see Table 3 and section 2.5).\textsuperscript{67,68} The prognosis of patients experiencing cardiotoxicity with these drugs is difficult to assess accurately, as most of these compounds are used in patients with metastatic disease with limited life expectancy. However, one can speculate that if hypertension is controlled throughout therapy, some potential HF may be reduced. Similarly, if cardiac dysfunction develops, it can be reversible in a large number of patients with appropriate and intensive HF medication.\textsuperscript{69}

2.1.1.5 Inhibition of BCR-ABL kinase

The inhibition of BCR-ABL kinase by small molecules such as imatinib has profoundly improved the prognosis of patients with several forms of chronic leukaemia and some forms of gastrointestinal stromal tumours. Although initial reports suggested a risk for imatinib-induced cardiotoxicity, analysis of large cohorts did not confirm these data.\textsuperscript{70} Newer, more potent inhibitors of BCR-ABL, such as nilotinib and ponatinib, have also demonstrated an association with cardiovascular events.\textsuperscript{74,75}

2.1.1.6 Proteasome inhibitors

Proteasome inhibitors are a relatively new line of treatment for multiple myeloma. Bortezomib and carfilzomib are the two clinically available drugs potentially causing cardiac dysfunction. Proteasomes, protein complexes responsible for degrading dysfunctional or unnecessary proteins, have an important maintenance function in the cardiomyocyte, and cardiac dysfunction and other cardiac issues may be expected if this maintenance function is impaired.\textsuperscript{76} The incidence of HF under bortezomib is relatively low (up to 4%) compared with carfilzomib, although it is sometimes aggravated by the concomitant use of steroids.\textsuperscript{77} Carfilzomib is a more potent and irreversible proteosomal inhibitor, and preliminary data suggest a substantially higher risk of HF (up to 25%).\textsuperscript{78,79}

2.1.1.7 Radiotherapy

The actual incidence of radiation-induced cardiotoxicity is difficult to evaluate for several reasons. These include the long delay between exposure and clinical manifestation of heart disease, the use of concomitant cardiotoxic chemotherapy, continuous improvements in radiation techniques and changes in the treated population and failure to attribute cardiac disease to previous radiotherapy despite increasing awareness of cardiovascular physicians of its long-term side effects. Some studies found a relative risk of fatal cardiovascular events between 2.2 and 12.7 in survivors of Hodgkin lymphoma and between 1 and 2.2 in patients with breast cancer. 80,81 The absolute excess risk of mortality ranges from 9.3 to 28 per 10 000 person-years of follow-up. 80 Among survivors, the risk of HF was increased 4.9-fold. 81 In patients with breast cancer treated in the era 1980–2000, the risk of cardiotoxicity was highest in patients treated with both left breast radiotherapy and cardiotoxic chemotherapy, suggesting a synergistic effect on cardiac risk. 82 Marked interstitial myocardial fibrosis is common in radiotherapy-induced cardiotoxicity, with lesions of variable volumes and distribution. 80 In 1820 adult survivors of childhood cancer (median age 31 years; median time from diagnosis 23 years) exposed to anthracycline chemotherapy (n = 1050), chest-directed radiotherapy (n = 306) or both (n = 464), 22% of survivors exposed to radiotherapy alone had evidence of diastolic dysfunction and 27.4% showed reduced exercise capacity (<490 m 6-min walk). 83 Systolic dysfunction is generally observed when radiotherapy is combined with anthracyclines. HF may also be aggravated by concomitant radiation-induced valvular heart disease (VHD) and CAD, and can evolve over years.

2.1.2 Diagnostic and therapeutic management

2.1.2.1 Screening, risk stratification and early detection strategies

The first step to identify patients at increased risk for cardiotoxicity consists of a careful baseline assessment of cardiovascular risk factors (Table 4). A limited number of studies have generated risk scores for different oncology patient cohorts. 93,84 However, none of these risk scores has been validated prospectively, and clinical judgement is required when evaluating the risk at an individual level. Risk assessment should include clinical history and examination and baseline measurement of cardiac function. Cardiac biomarkers (natriuretic peptides or troponins) may be considered in addition, preferably using the same assay that will be used during follow-up measurements, to increase comparability. It is critical to detect subclinical cardiac abnormalities, which may influence clinical decisions regarding the choice of chemotherapy, indication for cardioprotection or increased surveillance frequency (e.g. asymptomatic LV dysfunction). Finally, baseline assessment of cardiovascular risk factors allows appropriate interpretation of subsequent results/changes during regular monitoring. Baseline risk factors for cardiotoxicity are summarized in Table 4.

The same imaging modality and/or biomarker assay should be considered: expertise and availability, and several important core principles should be considered:
• The same imaging modality and/or biomarker assay should be used for continued screening throughout the treatment pathway.
• Switching between modalities or assays is strongly discouraged.

Strategies for screening and detection of cardiotoxicity include cardiac imaging [echocardiography, nuclear imaging, cardiac magnetic resonance (CMR)] and biomarkers (troponin, natriuretic peptides) (see Table 6). The choice of modalities depends upon local expertise and availability, and several important core principles should be considered:

- Modalities and tests with the best reproducibility are preferred.
- Imaging modalities that provide additional relevant clinical information are preferred (e.g., right ventricular function, pulmonary pressures, valvular function, pericardial evaluation).
- High quality radiation-free imaging is preferred, if available.

The precise timing and frequency of imaging and/or biomarker sampling will depend upon the specific cancer treatment, total cumulative dose of cardiotoxic chemotherapy, delivery protocol and duration and the patient’s baseline cardiovascular risk.

2.1.2.2 Cardiovascular management of patients treated with anthracyclines

For patients treated with adjuvant anthracyclines, baseline cardiac function should be assessed. If systolic dysfunction or significant VHD is found, the patient should be discussed with the oncology team and options for non-anthracycline-containing chemotherapy and/or cardioprotection should be considered. If used, a second assessment of cardiac function should be performed at the end of the treatment, particularly when the patient has an increased risk for cardiotoxicity or consecutive treatment with potentially cardiotoxic targeted therapies will follow. For higher-dose anthracycline-containing regimens and in patients with high baseline risk, earlier assessment of cardiac function after a cumulative total doxorubicin (or equivalent) dose of 240 mg/m² should be considered (see Table 5).

Measurement of at least one cardiac biomarker—high-sensitivity troponin (I or T) or a natriuretic peptide—may be considered at baseline, and determination of high-sensitivity troponin I has been suggested with each cycle of anthracycline-containing chemotherapy. To date, this suggested strategy has not been validated to prevent or improve longer-term toxicity events, but elevation

of cardiac biomarkers identifies patients at greater risk for cardiotoxicity who may benefit from measures to prevent cardiotoxicity.

2.1.2.3 Cardiovascular management of patients treated with anti-HER2

Patients receiving anti-HER2 therapies frequently, though not always, receive anthracyclines before starting the targeted therapy. In such cases, surveillance should begin before anthracycline administration. Standard screening during treatment depends on local protocols and recommendations, but typically cardiac monitoring is performed every 3 months during and once after completion of anti-HER2 treatment. Some investigators found that the rate of clinically relevant trastuzumab-induced cardiac dysfunction is substantially lower when a confirmatory LV assessment is carried out 3 weeks after an initial (asymptomatic) LVEF decrease. Several studies have demonstrated an improvement in early detection of LVEF decrease when troponins and speckle tracking echocardiography are used every 3 months during adjuvant trastuzumab treatment. Given the variability in timing of trastuzumab-induced LV dysfunction, measurement of troponin with every cycle may be considered in patients with high baseline risk.

2.1.2.4 Cardiovascular management of patients treated with VEGF inhibitors

The optimal timing of surveillance strategies for the various VEGF inhibitors known to cause myocardial dysfunction still needs to be clarified. After baseline assessment, some patients appear to develop LV dysfunction early after treatment onset, whereas in others this is delayed for several months. If baseline risk is high, it may be appropriate to consider early clinical follow-up in the first 2–4 weeks after starting targeted molecular therapy with, for example, sunitinib, sorafenib or pazopanib. Thereafter, the drug labels for all of these drugs suggest a periodic reassessment of cardiac function, but do not state specifically when and how. Currently, it is reasonable to consider periodic echocardiography, for example, every 6 months until stability in LVEF values is achieved. However, limited evidence is available to support any specific surveillance strategy. One observational study suggested surveillance every 2–3 months with troponin or N-terminal pro-B-type natriuretic peptide (NT-proBNP), and echocardiography detected myocardial toxicity in 33% of patients taking VEGF inhibitors for renal cell carcinoma.

2.1.2.5 Screening and early detection strategies

All patients receiving cardiotoxic chemotherapy should undergo a cardiac assessment, including LV function, during follow-up after treatment completion. A recent study reported a 9% incidence of LV impairment following anthracycline chemotherapy in a large unselected cohort of 2625 patients, detectable in 98% of cases within 12 months following the last chemotherapy cycle. Long-term surveillance should be considered for those who developed evidence of cardiotoxicity during treatment and for those in whom cardioprotective medication has been initiated, to determine whether a trial of weaning is appropriate. Emerging data suggest that adults exposed to high cumulative anthracycline doses and/or chest radiotherapy should be offered lifelong surveillance, and this is now recommended for survivors of childhood cancers. Additionally, recommendations for monitoring survivors of adult-onset cancer are currently under development.

Baseline echocardiographic assessment of LV function is recommended before initiation of potentially cardiotoxic cancer treatment in all patients, irrespective of clinical history, in order to confirm baseline risk. For low-risk patients (normal baseline echocardiogram, no clinical risk factors), surveillance should be considered with echocardiography every 4 cycles of anti-HER2 treatment or after 200 mg/m² of doxorubicin (or equivalent) for treatment with anthracyclines. More frequent surveillance may be considered for patients with abnormal baseline echocardiography (e.g. reduced or low normal LVEF, structural heart disease) and those with higher baseline clinical risk (e.g. prior anthracyclines, previous MI, treated HF). Survivors who have completed higher-dose anthracycline-containing chemotherapy (≥ 300 mg/m² of doxorubicin or equivalent) or who developed cardiotoxicity (e.g. LV impairment) requiring treatment during chemotherapy may be considered for follow-up surveillance echocardiography at 1 and 5 years after completion of cancer treatment.

The optimal modality, extent and frequency of surveillance in adults exposed to cardiotoxic cancer treatment who were asymptomatic at the time of initial treatment remain unclear and are frequently based on expert consensus rather than trial data. Retrospective observational data in elderly patients with breast cancer treated with adjuvant anthracyclines show that the risk of developing congestive HF continues to increase through >10 years of follow-up. However, there was no such increase in risk of congestive HF in the long-term follow-up of patients treated with adjuvant anthracyclines followed by trastuzumab. This finding is most likely because the latter patients were substantially younger and therefore their risk of developing cardiotoxicity was lower. Based on these observations, it seems appropriate to conduct regular and long-term surveillance in elderly patients and in patients with risk factors for cardiotoxicity who have been treated with anthracyclines.

2.1.2.6 Diagnostic tools to detect myocardial toxicity

Electrocardiography. ECG is recommended in all patients before and during treatment. It is useful to detect any ECG signs of cardiotoxicity, including resting tachycardia, ST-T wave changes, conduction disturbances, QT interval prolongation or arrhythmias. However, these ECG abnormalities are not specific and can be related to other factors (see Table 10). Of note, these ECG changes can be transitory and are not related to the development of chronic cardiomyopathy.

Echocardiography. Echocardiography is the method of choice for the detection of myocardial dysfunction before, during and after therapy (see Table 6). Unless three-dimensional (3D) echocardiography is used, which is the best echocardiographic method for measuring LVEF when endocardial definition is clear, the two-dimensional (2D) biplane Simpson method is recommended for estimation of LV volumes and ejection fraction in these patients. Cancer therapeutics-related cardiac dysfunction (CTRCD) is defined as a decrease in the LVEF of >10 percentage points to a value below the lower limit of normal. This decrease should be confirmed by repeated cardiac imaging done 2–3 weeks after the baseline diagnostic study showing the initial decrease in LVEF. The LVEF decrease may be further categorized as asymptomatic or symptomatic, or with regard to reversibility. Although the exact interval is not established, echocardiographic examination should be repeated during follow-up to confirm recovery, or to detect irreversible LV dysfunction. Echocardiography can also detect other complications.
of cancer therapy, including valvular and pericardial diseases and findings suggestive of pulmonary hypertension.98,99

The main limitation of 2D echocardiography is its relatively moderate reproducibility, which can be improved by the use of 3D echocardiography. The latter is associated with the best day-to-day reproducibility,100 but remains dependent on image quality, availability and operator experience. For serial evaluation of patients with cancer, LVEF measurements should ideally be performed by the same observer with the same equipment to reduce variability.85

Other useful echocardiographic techniques include contrast echocardiography, indicated in patients with suboptimal echocardiograms to improve delineation of the LV endocardial borders. Stress echocardiography may be helpful in the evaluation of patients with intermediate or high pretest probability for CAD, but no data are available with regard to its prognostic value in patients with cancer for HF prediction. Doppler myocardial imaging and deformation imaging is a promising tool and its use should be considered whenever possible. Several recent studies have shown the value of deformation imaging for early detection of LV dysfunction secondary to cancer therapy.92 Global systolic longitudinal myocardial strain (GLS) has been reported to accurately predict a subsequent decrease in LVEF.101,102 A relative percentage reduction of GLS of >15% from baseline is considered abnormal and a marker of early LV subclinical dysfunction. Until standardization of strain imaging through different vendors is fully achieved, the current recommendation is to use the same equipment for the longitudinal follow-up of patients with cancer to facilitate the interpretation of results. These advanced echocardiographic measurements are preferred, when available, to serve as the basis for clinical decisions when performed with adequate expertise at laboratories doing cardiac safety studies.103Diastolic dysfunction is common in patients with cancer, both at baseline and during treatment; however, no evidence has shown that treatment should be stopped based on these findings.

Nuclear cardiac imaging. Evaluation of LV function using multigated radionuclide angiography has been used for years to diagnose chemotherapy-induced cardiotoxicity with good accuracy and reproducibility,104 and few technical limitations. However, it is constrained by radiation exposure and provides only limited additional information on cardiac structure and haemodynamics (see Table 6). As echocardiography and multigated radionuclide angiography have different reference values, the same technique should be performed for baseline and follow-up studies.105,106

Cardiac magnetic resonance. CMR is a helpful tool for the evaluation of cardiac structure and function. It is useful to determine the cause of LV dysfunction and to clarify left and right ventricular function in challenging cases (i.e. borderline or contradictory results from other imaging modalities).93,107 It also serves to evaluate the pericardium, especially in patients with chest irradiation. Late gadolinium imaging may be useful to detect scarring or fibrosis, which may have prognostic implications in the context of impaired LV function.108,109 Additionally, CMR is an excellent test for the comprehensive evaluation of cardiac masses and infiltrative conditions. Use of unique tissue characterization capabilities of CMR (e.g. inflammation and oedema) will be dependent on acceptance of T2 and T1 mapping and extracellular volume fraction quantification (see Table 6). Diffuse anthracycline fibrosis cannot be evaluated with conventional techniques of late gadolinium enhancement.107

Cardiac biomarkers. The use of cardiac biomarkers during cardio-toxic chemotherapy may be considered in order to detect early cardiac injury (see Table 6). The challenge with the available published data is the timing of the laboratory assessment relating to chemotherapy, the definition of the upper limit of normal for a specific test, the use of different laboratory assays, as well as the challenge of the strategy to undertake in case of an abnormal result.86,110 There is currently no clear evidence to withhold or interrupt chemotherapy or targeted therapies based on a new abnormal cardiac biomarker result, particularly with the application of increasingly sensitive assays. However, an abnormal biomarker result is indicative of an increased risk of cardiotoxicity.

Single-centre studies show, in patients receiving high-dose combination chemotherapy, that a newly elevated cardiac troponin I from a normal baseline may identify those who develop cardiac dysfunction with a poor prognosis, particularly when troponin elevation persists, and who may benefit from treatment with ACE inhibitors.111–113 In patients treated with trastuzumab, particularly when previously exposed to anthracyclines, troponin I elevation can identify patients who will develop cardiac dysfunction and who will not recover despite treatment for HF.98

New elevation of serum troponin I detected with high-sensitivity troponin I assays in patients receiving anthracyclines and/or trastuzumab predicts subsequent LV dysfunction.89 In patients with breast cancer, a small study demonstrated that the combination of high-sensitivity troponin with GLS might provide the greatest sensitivity (93%) and negative predictive value (91%) to predict future cardiotoxicity.101

The role of cardiac biomarkers to detect cardiotoxicity due to targeted molecular therapies including trastuzumab is still unclear. Evidence supporting surveillance using troponin to predict future LV dysfunction with the use of other immune and targeted cancer therapies is still limited.

The use of natriuretic peptides to detect HF is widely established, and even very low levels can identify high-risk patients and guide therapy.113 In the context of chemotherapy, B-type natriuretic peptide (BNP) and NT-proBNP may be useful, but their role in routine surveillance to define the high-risk patient is not established.114 Future research needs to determine the optimal timing of biomarker measurement for different chemotherapies and confirm upper limits for each assay to better guide clinicians.

Surveillance and treatment strategies. The timing of cardiotoxicity surveillance using echocardiography and biomarkers needs to be personalized to the patient in the context of their baseline cardiovascular risk and the specific cancer treatment protocol prescribed. The most important element is risk stratification to guide the frequency of assessment and ensure that higher-risk patients have an earlier review to avoid missing early toxicity.115 This is based on expert opinion, and evidence is lacking regarding the optimal surveillance strategy to positively impact clinical outcomes. Future research needs to establish the optimal timing of biomarker measurement for the different cancer treatment pathways, confirm upper limits for each assay and better guide clinicians to target cardioprotective therapy to the appropriate patients with cancer.

Patients who develop asymptomatic LV dysfunction or HF during cancer therapy are likely to profit from ACE inhibitors or angiotensin II receptor blockers (ARBs) and beta-blocker treatment similar to the general HF population.116 More specifically, patients with
anthracycline-induced cardiotoxicity have a better cardiac outcome when treated with ACE inhibitors and/or beta-blockers early after detection of cardiac dysfunction, and combination therapy may be more effective than either treatment alone.36,38

2.1.3 Key points

- Cancer patients treated with potentially cardiotoxic therapy are at high risk of developing HF and should therefore receive medical care aimed at obtaining strict control of cardiovascular risk factors.
- LVEF should be determined before and periodically during treatment for early detection of cardiac dysfunction in patients receiving potentially cardiotoxic chemotherapy, with a method that provides sufficient image quality and, preferably, using the same method during follow-up.
- This group has decided to consider the lower limit of normal of LVEF in echocardiography as 50%, in line with the definition of cardiotoxicity commonly used in registries and trials in patients with cancer.
- A patient with a significant decrease in LVEF (e.g. a decrease >10%), to a value that does not drop below the lower limit of normal, should undergo repeated assessment of LVEF shortly after and during the duration of cancer treatment.
- If LVEF decreases >10% to a value below the lower limit of normal (considered as an LVEF <50%), ACE inhibitors (or ARBs) in combination with beta-blockers are recommended to prevent further LV dysfunction or the development of symptomatic HF, unless contraindicated, as these patients are at high risk of developing HF.
- ACE inhibitors (or ARBs) and beta-blockers are recommended in patients with symptomatic HF or asymptomatic cardiac dysfunction unless contraindicated.

2.2 Coronary artery disease

2.2.1 Pathophysiology and clinical presentation

Myocardial ischaemia and, to a lesser degree, infarction and ischaemia-induced arrhythmias are side effects of several cancer therapies. The mechanisms by which these drugs cause myocardial ischaemia are diverse and range from a direct vasospastic effect to endothelial injury and acute arterial thrombosis, to long-term changes in lipid metabolism and consequent premature arteriosclerosis (Table 7). Previous mediastinal radiotherapy may accelerate drug-related coronary damage.

2.2.1.1 Fluoropyrimidines

Fluoropyrimidines such as 5-fluorouracil (5-FU) and its oral form capecitabine are used to treat patients with gastrointestinal and other malignancies. The incidence of myocardial ischaemia varies considerably and may be as high as 10%, depending on dose, scheduling and route of administration.117 The mechanisms of 5-FU-induced myocardial ischaemia are multifactorial and include coronary vasospasm and endothelial injury.115 Chest pain and ischaemic ECG changes typically occur at rest, and less frequently during exercise, within days of drug administration and sometimes persist even after treatment cessation. However, the problem of fluoropyrimidine-induced myocardial ischaemia may be clinically underestimated; a recent study found silent ischaemia in ~6–7% of 5-FU-treated patients examined using a stress test.118 5-FU can also result in acute myocardial infarction.118

2.2.1.2 Cisplatin

Cisplatin may induce arterial thrombosis with subsequent myocardial and cerebrovascular ischaemia in ~2% of patients.119 The pathophysiology is multifactorial, including procoagulant and direct endothelial toxic effects. Cisplatin-treated survivors of testicular cancer have a higher incidence of CAD, with an absolute risk of up to 8% over 20 years.120,121

2.2.1.3 Immune and targeted therapeutics

Among the immune and targeted therapeutics, those inhibiting the VEGF signalling pathway have an increased risk for coronary thrombosis. VEGF signalling is important for endothelial cell survival, and inhibition can induce endothelial injury. The incidence of arterial thrombosis varies depending on the compound and disease studied; for the monoclonal VEGF antibody bevacizumab, it ranges from <1% in the setting of adjuvant breast cancer to 3.8% in metastatic diseases.120,122 A recent meta-analysis on the risk of arterial thrombosis induced by anti-VEGF small molecule TKIs found an overall

incidence of 1.7% for sorafenib and 1.4% for sunitinib. Sorafenib has also been reported to induce vasospasm.  

2.2.1.4 Radiotherapy
Supradiaphragmal and, in certain patient groups, even infradiaphragmal radiotherapy may be associated with a higher incidence of ischaemic heart disease through the development of severe atherosclerotic and non-atherosclerotic disease, complicated by plaque rupture and thrombosis, and potentially with coronary spasm. Ostial lesions are frequent and a potentially life-threatening complication. The most exposed coronaries are the left anterior descending during left breast irradiation and the left main stem, circumflex and right coronary arteries during treatment for Hodgkin lymphoma. A higher prevalence of stress test abnormalities has been found among women irradiated for left breast cancer compared with right-sided cancer. The evolution may be rapid, with acute coronary syndrome or sudden death as initial manifestations, but it is more often asymptomatic for a long time. Radiation-related cardiac disease in patients with lymphoma typically manifests 15–20 years after the initial treatment, and younger patients are more susceptible than older patients. Survivors of Hodgkin lymphoma have a four- to seven-fold increased risk of CAD compared with the general population and a cumulative incidence of CVD up to 50% 40 years after treatment. Based on these data, it appears appropriate to screen regularly for cardiac diseases patients who received radiation therapy, starting 10–15 years after the initial cancer treatment and continuing lifelong. The risk of developing CAD or CAD-associated events after chest irradiation is modifiable by several factors, including concomitant chemotherapy with anthracyclines, young age, high-fractionated doses, lack of thoracic shielding, cardiovascular risk factors and established CAD. The risk of myocardial infarction in patients treated for Hodgkin lymphoma is two- to seven-fold higher than in the general population, with a cumulative incidence of 10% at 30 years.

2.2.2 Diagnostic and therapeutic management
The identification of patients with pre-existing CAD and other CVDs is of paramount importance before initiating cancer treatment. Data suggest that pre-existing CAD substantially increases the risk of developing treatment-related CAD. In addition, patients who develop an acute coronary syndrome or symptomatic CAD while thrombocytopenic during chemotherapy pose a particular challenge for treatment and need case-by-case multidisciplinary management. Options for medical and interventional therapies are limited, as the use of antiplatelet drugs and anticoagulants is frequently not possible or must be restricted. In patients treated by percutaneous coronary intervention who are subsequently found to have a malignancy, minimal duration of dual antiplatelet therapy should be pursued as far as reasonable, according to the most recent guidelines, to limit bleeding risk. The diagnostic algorithms used to identify CAD in patients with cancer are the same as in patients without cancer, and echocardiography should be included as part of the diagnostic workup in these patients. The incidence and onset of CAD after radiation therapy is dose dependent; historically, thoracic doses of $\geq 30$ Gy were considered to cause vascular disease. However, newer data indicate that substantially lower radiation doses increase the risk of subsequent CAD, and traditional risk factors for atherosclerosis magnify the risk even more, expanding the population at risk. Typically there is a long latency period with asymptomatic CAD after radiation treatment and patients may become symptomatic $\sim 10$ years after the initial cancer therapy. Presentation of CAD is more often atypical and the prevalence of silent ischaemia may be higher than in conventional patients with CAD, possibly because of concomitant neurotoxicity of radiotherapy, or chemotherapy affecting the patient’s perception of angina. Sudden cardiac death in irradiated patients has been reported and linked to diffuse intimal hyperplasia of all coronary arteries or to significant left main stenosis. It is difficult to predict the burden of radiation-induced CAD in the future, as the introduction of contemporary heart-sparing radiation techniques should attenuate the problem. These measures include a reduction in dose, tangential fields and shielding of cardiac structures.

Long-term complications of treatment for testicular cancer include a greater than two-fold increased risk of CAD $\sim 10$ years after the initial treatment. These patients, who are typically in their 20s or 30s when affected by the cancer, are commonly treated with a multidrug cisplatin-based chemotherapy with or without radiation therapy. After almost 20 years of follow-up, compared with patients treated with surgery only, patients treated with chemotherapy and/or (sub)diaphragmatic) radiation have more cardiovascular risk factors and an 8% absolute risk for ischaemic events.

2.2.3 Key points
- Assessment of CAD should be based on the history, age and gender of the patient, considering the use of chemotherapy drugs as a risk factor for CAD.
- Clinical evaluation and, when necessary, testing for detection of myocardial ischaemia is key to identify patients with latent pre-existing CAD. This may have implications in the selection of cancer treatment.
- Patients treated with pyrimidine analogues should be closely monitored for myocardial ischaemia using regular ECGs, and chemotherapy should be withheld if myocardial ischaemia occurs.
- Drug rechallenge after coronary vasospasm should be reserved for when no other alternatives exist, and only under prophylaxis and close monitoring of the patient. Pretreatment with nitrates and/or calcium channel blockers may be considered in this setting.
- Long-term clinical follow-up and, when required, testing for the presence of CAD may be useful to identify patients with cardiac disease who develop long-term complications of chemotherapy and radiotherapy.

2.3 Valvular disease
2.3.1 Pathophysiology and clinical presentation
Chemotherapeutic agents do not directly affect cardiac valves, but VHD may be observed in patients with cancer for several reasons, including pre-existing valve lesions, radiotherapy, infective endocarditis and secondary to LV dysfunction. Radiation-induced VHD has been reported as common, affecting $\sim 10\%$ of treated patients, and includes fibrosis and calcification of the aortic root.
aortic valve cusps, mitral valve annulus and the base and mid portions of the mitral valve leaflets, sparing the mitral valve tips and commissures, allowing distinction from rheumatic disease. In patients with Hodgkin lymphoma, radiation dose to the heart valves can increase the risk of clinically significant VHD as the first cardiovascular event after treatment, especially at doses >30 Gy. However, for patients with mediastinal involvement treated today with 20 or 30 Gy, the 30-year risk would be increased only by ~1.4%.146

2.3.2 Diagnostic and therapeutic management
Echocardiography is the assessment method of choice, and 3D echocardiography may be useful, particularly for the evaluation of mitral valve commissures. Baseline and repeated echocardiography after radiation therapy involving the heart are recommended in patients with cancer for the diagnosis and follow-up of VHD. Echocardiography may be useful, particularly for the evaluation of patients with cancer for the diagnosis and follow-up of VHD. Echocardiography is the assessment method of choice, and 3D echocardiography may be useful, particularly for the evaluation of mitral valve commissures. Baseline and repeated echocardiography after radiation therapy involving the heart are recommended in patients with cancer for the diagnosis and follow-up of VHD.

CMR and computed tomography (CT) may be used to assess the severity of VHD, but cardiac CT is mainly useful for detecting extensive calcifications of the ascending aorta, which may lead to a higher operative risk and sometimes prohibit conventional cardiovascular surgery. Cardiac surgery is also frequently challenging in such patients because of mediastinal fibrosis, impaired wound healing and associated coronary artery, myocardial and pericardial disease. Transcatheter valve implantation (e.g. transcatheter aortic valve implantation) may be a suitable option in this situation.

2.4 Arrhythmias
2.4.1 Pathophysiology and clinical presentation
Patients with cancer may experience a wide spectrum of cardiac arrhythmias, including sinus tachycardia, bradyarrhythmias or tachyarrhythmias, and conduction defects, some of which may cause severe symptoms or become life-threatening or impose a change in the patient’s treatment plan (Table 8). Arrhythmias can be present at baseline in 16–36% of treated patients with cancer.

2.4.1.1 QT prolongation
QT prolongation can be caused by cancer therapies (Table 9), electrolyte disturbances, predisposing factors and concomitant medications (e.g. anti-emetics, cardiac medications, antibiotics, psychotropes). QT prolongation can lead to life-threatening arrhythmias such as torsade de pointes. The duration of the QT interval and risk factors for QT prolongation should be controlled before, during and after cancer treatment. The risk of QT prolongation varies with different drugs, with arsenic trioxide being the most relevant. This drug, which is used to treat some leukaemias and myelomas, prolongs the QT interval in 26–93% of patients, and life-threatening ventricular tachyarrhythmias have been reported not infrequently. Prolongation of the QTc interval was observed 1–5 weeks after arsenic trioxide infusion and then returned towards baseline by the end of 8 weeks, i.e. before the second course of chemotherapy. Other cancer therapies that frequently induce QT prolongation are listed in Table 9. Among these, the TKI drug class, and specifically vandetanib, has the second highest incidence of QT prolongation.

2.4.1.2 Supraventricular arrhythmia
Any type of supraventricular arrhythmia may arise acutely during or even after chemotherapy or radiotherapy, of which atrial fibrillation is the most common. The arrhythmia may be related to co-morbidities or due to direct tumour effects, LV dysfunction or toxic effects of the cancer treatment. The most common form of cancer-related atrial fibrillation is postoperative atrial fibrillation, particularly in patients undergoing lung resection. An overview of pathogenetic mechanisms has been published.

2.4.1.3 Ventricular arrhythmias
Ventricular arrhythmias can be related to QT prolongation, to acute and chronic toxicity of chemotherapy and radiotherapy.
Sinus node dysfunction and conduction defects may arise following radiotherapy and are often permanent. Paclitaxel and thalidomide can result in sinus node dysfunction and bradyarrhythmias and heart block.\(^{151}\)

### 2.4.2 Diagnostic and therapeutic management

Arrhythmias in patients with cancer can occur before, during and shortly after treatment. Management should be individualized and decisions on the use of anti-arrhythmic drugs or device therapy (implantable or external wearable cardioverter defibrillators)\(^{156}\) should consider the competing risks of cardiac- and cancer-related life expectancy, quality of life and complication risks.

#### 2.4.2.1 QT interval and associated risk factors for QT prolongation

The QT interval and associated risk factors for QT prolongation (Table 10) should be assessed before and during treatment. QTc intervals >450 ms in men and >460 ms in women are suggested as a guideline for the upper limit of normal on baseline ECG evaluation.\(^{156,157}\) QTc prolongation >500 ms and a ΔQT (i.e. change from baseline) of >60 ms are considered to be of particular concern because torsades de pointes rarely occurs when QTc is <500 ms.\(^{156}\) ECG and electrolyte monitoring during treatment

LQTS = long QT syndrome.
should be considered at baseline, 7–15 days after initiation or changes in dose, monthly during the first 3 months and then periodically during treatment depending on the chemotherapy drug and patient status. Patients experiencing diarrhoea should be monitored more frequently, and those receiving treatment with arsenic trioxide should be monitored weekly with ECG.

Management is generally dependent on correcting the predisposing factors (e.g. concomitant electrolyte abnormalities, QT-prolonging drugs). A full list of QT-prolonging drugs and which concomitant drugs should be avoided whenever possible can be found at [http://www.crediblemeds.org](http://www.crediblemeds.org). A general recommendation from the US Food and Drug Administration and European Medicines Agency is that if during treatment QTc is >500 ms (or QTc prolongation is >60 ms above baseline), treatment should be temporarily interrupted, electrolyte abnormalities corrected and cardiac risk factors for QT prolongation controlled. If no alternative therapy exists, the frequency of ECG monitoring of the QT interval should be increased. The frequency of monitoring should be individualized depending on the patient’s characteristics and the causative drug.

The development of bursts of torsade de pointes is unusual, but requires intravenous administration of magnesium sulphate (10 mL) and, in some acute situations, overdrive transvenous pacing or isoprenaline titrated to a heart rate >90 beats per minute to prevent new episodes in the acute setting. If sustained ventricular arrhythmias and haemodynamic instability occur, non-synchronized defibrillation must be performed.

### 2.4.3 Key points

- A 12-lead ECG should be recorded and the QT interval, corrected for heart rate with Bazett’s or Fridericia’s formula, should be obtained in all patients at baseline.
- Patients with a history of QT prolongation, relevant cardiac disease, treated with QT-prolonging drugs, bradycardia, thyroid dysfunction or electrolyte abnormalities should be monitored by repeated 12-lead ECG.
- Consider treatment discontinuation or alternative regimens if the QTc is >500 ms, QTc prolongation is >60 ms or dysrhythmias are encountered.
- Conditions known to provoke torsades de pointes, especially hypokalaemia and extreme bradycardia, should be avoided in patients with drug-induced QT prolongation.
- Exposure to other QT-prolonging drugs should be minimized in patients treated with potentially QT-prolonging chemotherapy.

#### 2.4.3.1 Atrial fibrillation and atrial flutter

The initial approach to the management of atrial fibrillation and atrial flutter requires the usual decisions regarding rhythm management, thromboembolic prophylaxis and effective stroke prevention with oral anticoagulation. However, the balance between thromboembolic and bleeding risks of atrial fibrillation (as assessed by the CHA₂DS₂-VASc [Congestive heart failure or left ventricular dysfunction, Hypertension, Age ≥75 years (doubled), Diabetes, Stroke (doubled), Vascular disease, Age 65–74 years, Sex category (female)] and HAS-BLED [Hypertension, Abnormal renal/liver function (1 point each), Stroke, Bleeding history or predisposition, Labile international normalized ratio, Elderly (>65 years), Drugs/alcohol] scores, respectively) is particularly challenging in patients with cancer. While cancer may cause a prothrombotic state, it may also predispose to bleeding. On the other hand, the CHA₂DS₂-VASc and HAS-BLED risk scores have not been validated in patients with cancer. Thus the decision on antithrombotic therapy for stroke prevention may be quite challenging and should not be based only on the risk assessment scores used for the general population.

In patients with a CHA₂DS₂-VASc score ≥2, anticoagulation can generally be considered if the platelet count is >50 000/mm³, usually with a vitamin K antagonist and with good anticoagulation control (with time in the therapeutic range >70%). Close liaison with haematologists/oncologists is advised. The occurrence of atrial fibrillation at any point (e.g. during chemotherapy, surgery or radiotherapy) suggests an intrinsic predisposition to arrhythmia. In terms of thromboprophylaxis, this again depends on the presence of stroke risk factors, where anticoagulation would be recommended with a CHA₂DS₂-VASc score ≥2. Even with lower-risk patients with atrial fibrillation, prophylaxis may be considered, given the risk of venous thromboembolism (VTE) in patients with cancer.

Full assessment of the patient, including echocardiography, is advised, and decisions on anticoagulation should consider other co-morbidities, bleeding risks and patient values and preferences. Anticoagulation options include therapeutic low molecular weight heparin (LMWH) (as a short- to intermediate-term measure), a vitamin K antagonist (VKA; e.g. warfarin) if the international normalized ratio control is stable and effective or a non-VKA oral anticoagulant (NOAC). Warfarin is often avoided in cancer patients with metastatic disease and high bleeding risk, with LMWH the traditionally preferred option, given the risk for variations in the international normalized ratio. The role and safety of NOACs in this patient group remains to be clarified. Although trials generally excluded patients with a platelet count of <100 000/mm³ or limited survival, a meta-analysis of the patients with cancer in NOAC trials suggested these new drugs are safe.

Generally, an individualized approach to the management of atrial fibrillation is needed, and decisions on rate or rhythm control should be patient-centred and symptom directed. A beta-blocker or non-dihydropyridine calcium channel blocker may help with rate control in atrial fibrillation and with suppression of supraventricular tachycardia. Digitalis may be considered as an alternative in patients with intolerance to the former, with systolic dysfunction or HF.

#### 2.4.3.2 Bradycardia or atrioventricular block

The development of bradycardia or atrioventricular block requires intravenous administration of magnesium sulphate (10 mL) and, in some acute situations, overdrive transvenous pacing or isoprenaline titrated to a heart rate >90 beats per minute to prevent new episodes in the acute setting. If sustained ventricular arrhythmias and haemodynamic instability occur, non-synchronized defibrillation must be performed.

#### 2.5 Arterial hypertension

##### 2.5.1 Pathophysiology and clinical presentation

Hypertension is a frequent co-morbidity in patients with cancer. It can also be a causative factor, such as in renal cancer.
inhibitors have a high risk (11–45%) of inducing new hypertension or destabilizing previously controlled hypertension, including severe hypertension in 2–20% of cases.\textsuperscript{161,162} The incidence and severity depend upon patient age, history of hypertension, CVD history, type of cancer (i.e. renal vs. non-renal cell cancer), drug type and dose, schedule used and associated cancer therapies. In a meta-analysis of clinical trials, the incidence of hypertension was increased by a factor of 7.5, 6.1 and 3.9, respectively, under bevacizumab, sorafenib and sunitinib.\textsuperscript{563} A summary of the incidence of hypertension reported in patients with cancer taking these drugs can be found in the appendix at the end of this document. Nitric oxide pathway inhibition, vascular rarefaction (i.e. reduced number of vessels), oxidative stress and glomerular injury developing from loss of VEGF effect represent some of the main proposed mechanisms.\textsuperscript{162,164} VEGF inhibition may also cause renal thrombotic microangiopathy.\textsuperscript{164} Drug-related hypertension can occur from initiation until 1 year after treatment onset. In the case of sunitinib, cancer efficacy may be correlated with the occurrence and degree of hypertension, but there is no evidence that antihypertensive therapy impairs oncology responses.\textsuperscript{9}

2.5.2 Diagnostic and therapeutic management

Management of hypertension aims at reducing the short-term risk of its related morbidities while maintaining effective anti-angiogenic therapy for optimal cancer treatment.\textsuperscript{165} The goal is to identify hypertension (\(>140/90\) mmHg) and maintain blood pressure (\(<140/90\) mmHg, or lower in case of overt proteinuria). Baseline assessment of CVD risk factors (including a history of hypertension and current blood pressure levels) and management of arterial hypertension should be performed before initiation of a VEGF inhibitor. Pain control and stress management are necessary for adequate estimation of blood pressure. Other medications used in these patients (e.g. steroids, non-steroidal anti-inflammatory drugs, erythropoietin) may also predispose to or cause hypertension. When white-coat hypertension is suspected, ambulatory blood pressure measurement should be considered and lifestyle modification encouraged.\textsuperscript{166}

After the initiation of VEGF inhibitors, early detection and reactive management of blood pressure elevations are necessary to avoid severe complications, and aggressive pharmacological management is recommended.\textsuperscript{167–171} ACE inhibitors, ARBs and non-diodehydroxyline calcium channel blockers (amlodipine, felodipine) are proposed as first-line therapies.\textsuperscript{172} ACE inhibitors and beta-blockers are the preferred antihypertensive drugs in patients with HF or at risk of HF or LV dysfunction.\textsuperscript{173} Because decreased nitric oxide signalling plays a key role in the pathogenesis of hypertension,\textsuperscript{169} drugs that increase nitric oxide signalling, such as the beta1-blocker nebivolol, may represent a valuable option in this population.\textsuperscript{116} Other beta-blockers with vasodilatory effects, such as carvedilol, can be considered. Diltiazem and verapamil inhibit cytochrome P450 3A4, and because many VEGF inhibitors are a substrate of this isoenzyme, this combination results in increased drug plasma levels and should therefore be avoided. Inhibitors of phosphodiesterase-5, such as sildenafil and tadalafil, may also offer an antihypertensive therapy option, although available data are limited in patients with arterial hypertension.\textsuperscript{174,175} Diuretics have the risk of electrolyte depletion and consequent QT prolongation and, although they may be used, caution is advised and they should not be considered as first-line therapy because VEGF inhibitors can produce severe diarrhoea and potential dehydration.\textsuperscript{9,172} However, there is minimal trial-based evidence suggesting a superiority of any specific class of antihypertensive drug in patients treated with these VEGF inhibitors.\textsuperscript{175,176}

Close monitoring and evaluation of treatment adherence are necessary when severe hypertension is present. To ensure efficacy and tolerance of antihypertensive drugs, follow-up is mandatory. Patients with resistant hypertension should be referred to cardiology or hypertension specialist assessment to minimize interruption of VEGF inhibitors.

2.5.3 Key points

- Hypertension should be adequately treated according to the current standing clinical practice guidelines, and blood pressure should be monitored before initiating cancer treatment and periodically during treatment, depending on the patient’s characteristics and adequate blood pressure control.
- Hypertension in patients with cancer is manageable with conventional antihypertensive treatment, but early and aggressive treatment is encouraged to prevent the development of cardiovascular complications (i.e. HF).
- ACE inhibitors or ARBs, beta-blockers and dihydroxyline calcium channel blockers are the preferred antihypertensive drugs. Non-diodehydroxyline calcium channel blockers should preferably be avoided due to drug interactions.
- Dose reduction and reinforcement of antihypertensive treatment or discontinuation of VEGF inhibitors can be considered if blood pressure is not controlled. Once blood pressure control is achieved, VEGF inhibitors can be restarted to achieve maximum cancer efficacy.

2.6 Thromboembolic disease

2.6.1 Pathophysiology and clinical presentation

Tumour cells can trigger coagulation through different pathways, including procoagulant, antifibrinolytic and pro-aggregating activities; release of pro-inflammatory and pro-angiogenic cytokines and interaction with vascular and blood cells through adhesion molecules.\textsuperscript{177}

2.6.1.1 Arterial thrombosis

Intra-arterial thrombotic events are rare in patients with cancer, with an incidence of \(\sim 1\%\). They occur mostly in metastatic pancreatic, breast, colorectal and lung cancers, under anthracyclines and taxane- and platinum-based chemotherapies, and affected patients have a poor prognosis.\textsuperscript{178} The prothrombotic state may facilitate embolic events secondary to atrial fibrillation (see section 2.4.3.1). Some cancer therapies, especially VEGF inhibitors, may favour thromboembolic complications\textsuperscript{9} (see section 2.2). In patients with breast cancer under hormonal therapy, higher rates of arterial thrombotic events are reported under aromatase inhibitors compared with tamoxifen, which are at least partly explained by the more favourable effects of tamoxifen on the lipid profile.\textsuperscript{179}

2.6.1.2 Venous thrombosis and thromboembolism

Venous thrombosis and VTE occur frequently in patients with cancer, may affect up to 20% of hospitalized patients and are frequently
they can be related to chemotherapy, including its administration route (use of indwelling venous catheters), and also to the cancer itself and the patient’s previous risk of venous thrombosis. VTE is the most common cause of death after surgery for cancer. Antithrombotic prophylaxis should be given for a minimum of 4 weeks after surgery. VTE is common in ambulatory patients with cancer (bladder, colon, ovary, lung, stomach and pancreas) during chemotherapy treatment; however, the role of prophylaxis is unclear. Improved patient selection and/or antithrombotic agents are required. Some biological factors are also considered as predictive of VTE in cancer (platelet count, leucocyte count, d-dimers, etc.). The combination of chemotherapy and VEGF inhibitors increases the risk of VTE and recurrent VTE six-fold and two-fold, respectively. In patients with breast cancer, higher rates of VTE are reported under tamoxifen compared with aromatase inhibitors. The management of these silent thrombotic events is still unclear. The detection of thrombotic events in patients undergoing chemotherapy is based mainly on clinical symptoms. No systematic screening strategy has shown any benefit. Incidental pulmonary embolism or venous thrombosis can be detected during imaging for cancer (e.g. chest positron emission tomography—computed tomography). The management of these silent thrombotic events is still unclear. As the risk for (symptomatic) recurrence and mortality is increased, these cases are usually treated in a similar manner to symptomatic VTE.

The decision to administer anticoagulation for VTE prevention in patients with cancer should always take into consideration the patient’s bleeding risk and life expectancy; these may change over time, requiring periodic reassessment. Treatment of a confirmed episode of acute VTE in haemodynamically stable patients consists of LMWH given over a period of 3–6 months. This strategy is superior to VKA therapy in patients with cancer in terms of reduced VTE events, with no difference regarding mortality or bleeding in clinical trials. Bleeding risk can be six times higher under anticoagulation for deep vein thrombosis in patients with vs. without cancer. Cancer is a strong risk factor for VTE recurrence. Consequently, chronic anticoagulation after the acute phase of treatment, and until the cancer is considered cured, should be considered. The choice of anticoagulation discontinuation or maintenance under LMWH or switching to VKAs should be discussed on an individual basis after considering the cancer therapy success, the risk of VTE recurrence and bleeding, as well as the patient’s preference. Current data on NOACs are limited to a subgroup analysis of patients with cancer within large trials comparing these drugs with VKAs in VTE. Overall, no differences were reported between NOACs and VKAs for either VTE recurrence or bleeding. Results from specific trials involving NOACs in patients with cancer are awaited. No comparison between NOACs and LMWH is currently available. Different NOACs may differ because of potential drug interactions and sensitivity to renal or hepatic dysfunction. Recurrent VTE may still occur despite VKA or LMWH therapy in patients with cancer, and may be managed by switching from VKA to LMWH or increasing the LMWH dose. A venous cava filter, either definitive or retractable, may be implanted when anticoagulation is contraindicated or failing. However, the risk of filter thrombosis and occlusion leading to distal propagation of thrombosis with post-thrombotic syndrome should be considered. No clinical advantage was found in the systematic placement of a vena cava filter in addition to anticoagulation with fondaparinux in patients with cancer.

There is no conclusive evidence on the benefits of thrombolysis in case of haemodynamically unstable pulmonary embolism in patients with cancer. Increased bleeding risk should be expected, but because of high pulmonary embolism—related early mortality risk, thrombolysis may still be considered, on a case-by-case basis, taking into account the patient’s quality-adjusted life expectancy related to the individual cancer. It is important to keep in mind contraindications to fibrinolytic therapy in patients with brain tumours or metastasis. Surgical embolectomy may be considered, but surgery imparts significant morbidity, and cardiopulmonary bypass requires aggressive anticoagulation.

The management of arterial thrombotic events in patients with cancer has been poorly addressed, and the use of antithrombotic therapies, thrombolysis and/or endovascular intervention should be discussed on a case-by-case basis with multidisciplinary consultation involving the cardio-oncology team, when available. In case of recurrences, control of cardiovascular risk factors and the search for anti-phospholipid antibodies has been proposed.

### 2.6.2. Diagnostic and therapeutic management

The detection of thrombotic events in patients undergoing chemotherapy is based mainly on clinical symptoms. No systematic screening strategy has shown any benefit. Incidental pulmonary embolism or venous thrombosis can be detected during imaging for cancer (e.g. chest positron emission tomography—computed tomography). The management of these silent thrombotic events is still unclear. As the risk for (symptomatic) recurrence and mortality is increased, these cases are usually treated in a similar manner to symptomatic VTE.

The decision to administer anticoagulation for VTE prevention in patients with cancer should always take into consideration the patient’s bleeding risk and life expectancy; these may change over time, requiring periodic reassessment. Treatment of a confirmed episode of acute VTE in haemodynamically stable patients consists of LMWH given over a period of 3–6 months. This strategy is superior to VKA therapy in patients with cancer in terms of reduced VTE events, with no difference regarding mortality or bleeding in clinical trials. Bleeding risk can be six times higher under anticoagulation for deep vein thrombosis in patients with vs. without cancer. Cancer is a strong risk factor for VTE recurrence. Consequently, chronic anticoagulation after the acute phase of treatment, and until the cancer is considered cured, should be considered. The choice of anticoagulation discontinuation or maintenance under LMWH or switching to VKAs should be discussed on an individual basis after considering the cancer therapy success, the risk of VTE recurrence and bleeding, as well as the patient’s preference. Overall, no differences were reported between NOACs and VKAs for either VTE recurrence or bleeding. Results from specific trials involving NOACs in patients with cancer are awaited. No comparison between NOACs and LMWH is currently available. Different NOACs may differ because of potential drug interactions and sensitivity to renal or hepatic dysfunction. Recurrent VTE may still occur despite VKA or LMWH therapy in patients with cancer, and may be managed by switching from VKA to LMWH or increasing the LMWH dose. A venous cava filter, either definitive or retractable, may be implanted when anticoagulation is contraindicated or failing. However, the risk of filter thrombosis and occlusion leading to distal propagation of thrombosis with post-thrombotic syndrome should be considered. No clinical advantage was found in the systematic placement of a vena cava filter in addition to anticoagulation with fondaparinux in patients with cancer.

There is no conclusive evidence on the benefits of thrombolysis in case of haemodynamically unstable pulmonary embolism in patients with cancer. Increased bleeding risk should be expected, but because of high pulmonary embolism—related early mortality risk, thrombolysis may still be considered, on a case-by-case basis, taking into account the patient’s quality-adjusted life expectancy related to the individual cancer. It is important to keep in mind contraindications to fibrinolytic therapy in patients with brain tumours or metastasis. Surgical embolectomy may be considered, but surgery imparts significant morbidity, and cardiopulmonary bypass requires aggressive anticoagulation.

The management of arterial thrombotic events in patients with cancer has been poorly addressed, and the use of antithrombotic therapies, thrombolysis and/or endovascular intervention should be discussed on a case-by-case basis with multidisciplinary consultation involving the cardio-oncology team, when available. In case of recurrences, control of cardiovascular risk factors and the search for anti-phospholipid antibodies has been proposed.

### 2.7. Peripheral vascular disease and stroke

#### 2.7.1 Pathophysiology and clinical presentation

**2.7.1.1 Peripheral artery disease**

Severe atherosclerotic and non-atherosclerotic peripheral artery disease (PAD) in the lower extremities can occur (in up to 30%) in patients treated with nilotinib, ponatinib or BCR-ABL TKIs used for chronic myeloid leukaemia, even in the absence of CVD risk factors.
2.8.1 Pathophysiology and clinical presentation

Pulmonary hypertension is a rare but serious complication of some cancer agents and stem cell bone marrow transplantation.\(^{203}\) The TKI imatinib improved haemodynamics in patients with advanced pulmonary veno-occlusive disease,\(^{207}\) involving predominantly small vessels.\(^{208}\) This condition appears 8–40 months after exposure to dasatinib, with clinical and haemodynamic presentation suggestive of PAH. Unlike other forms of PAH, this is often reversible after drug discontinuation or replacement with another TKI, such as nilotinib. Recently, cyclophosphamide and other alkylating agents were suggested as contributing to the development of pulmonary veno-occlusive disease,\(^{209}\) involving predominantly small venules and representing the most severe form of pulmonary hypertension lacking effective pharmacological treatment.

2.8.2 Diagnostic and therapeutic management

Baseline echocardiographic assessment, including the search for signs of right ventricular overload, should be considered in individuals requiring treatment with cancer drugs that can cause pulmonary hypertension (e.g. dasatinib) (Table 12). This approach may help in interpretation of follow-up echocardiographic examinations in patients reporting exercise limitation or exertional dyspnoea during cancer therapy. Patients with echocardiographic signs suggesting increased baseline pulmonary arterial pressure require cardiology assessment to determine its aetiology, as it may affect the strategy of cancer treatment, particularly when due to LV dysfunction or chronic thromboembolic pulmonary hypertension.\(^{208}\)

Non-invasive cardiovascular surveillance should be considered in all patients during treatment with cancer drugs known to cause PAH, particularly in case of the appearance of new exertional dyspnoea, fatigue or angina (Table 12). Echocardiography may be considered every 3–6 months in asymptomatic patients. It is unclear whether patients with baseline signs of right ventricular overload due to co-morbidities commonly associated with elevated pulmonary arterial pressure (e.g. chronic obstructive pulmonary disease, left heart dysfunction) are at higher risk of chemotherapy-induced PAH and require more frequent surveillance with echocardiography.

---

NT-proBNP = N-terminal fragment B-type natriuretic peptide; NYHA = New York Heart Association; PAH = pulmonary arterial hypertension; PAP = pulmonary arterial pressure; PH = pulmonary hypertension; WHO = World Health Organization.

---

See diagnostic algorithms for suspected PH in European Society of Cardiology (ESC)/European Respiratory Society (ERS) Guidelines on Pulmonary Hypertension (2015).\(^{206}\)

Datatinib-induced PH usually reversible with drug cessation.
When drug-induced PAH is suspected, referral to a specialized pulmonary hypertension team is recommended to assess indications for right heart catheterization. Multidisciplinary team discussions should be held with oncology or haematology regarding the risk–benefit ratio of continuing cancer treatment with PAH drug therapy vs. stopping or replacing the culprit drug. Dasatinib-induced pulmonary hypertension is often reversible with drug cessation, although usually without restoration of normal right heart haemodynamics. Targeted therapy for PAH is used temporarily or permanently.

2.9 Other cardiovascular complications of cancer treatment

2.9.1 Pericardial disease
Acute pericarditis may occur with the use of several chemotherapeutic drugs (predominantly anthracyclines, but also cyclophosphamide, cytarabine and bleomycin), while it has become uncommon during radiotherapy and is usually associated with pericardiac mediastinal tumours. Acute pericarditis with typical chest pain, fever, ST-T changes and large effusions, even leading to tamponade, may develop 2–145 months after thoracic radiotherapy, with an absolute cumulative incidence of 2–5%. Transthoracic echocardiography is the method of choice for the evaluation of patients with suspected pericardial disease due to chemotherapy, but CT can be of help, particularly to identify calcification. Treatment of pericardial effusion consists primarily of non-steroidal anti-inflammatory drugs and colchicine. Pericardiocentesis may be required for large effusions and those causing haemodynamic compromise, eventually followed by surgical pericardial windowing. Delayed pericardial disease may develop 6 months to 15 years after radiation treatment, and includes pericarditis and chronic pericardial effusion (usually asymptomatic). Although most cases resolve spontaneously, there are reports of occurrence of chronic and/or constrictive pericarditis after high-dose radiotherapy administration in up to 20% of patients.

2.9.2 Pleural effusion
Pleural effusion related to the cancer itself, HF, infections or other causes is common in patients with cancer. Some cancer drugs (e.g. dasatinib and imatinib) may induce fluid retention or a reversible pleural effusion through additional unknown mechanisms.

2.9.3 Autonomic dysfunction
Radiotherapy damage to the cardiac nervous system may lead to sympathetic–vagal imbalance characterized by inappropriate sinus tachycardia, altered heart rate variability and decreased sensitivity. This may lead to a higher pain threshold or silent ischaemia in cancer survivors with manifest CAD. Its management does not differ from that in non-cancer patients.

2.10 Cardiovascular complications of cancer treatment in special populations
Cardiotoxicity of cancer therapy has special characteristics in some clinical subgroups.

2.10.1 Paediatric cancer population
A steadily growing number of childhood cancer survivors have to face lifelong side effects of cancer therapies, some of them affecting the cardiovascular system. Indeed, the risk for severe cardiovascular conditions is increased eight-fold, putting cardiac disease among the leading causes of death in long-term survivors of childhood cancer. Anthracyclines and radiotherapy are the most commonly implicated cardiotoxic agents in childhood cancer. A recent large follow-up trial found cardiovascular complications in 8.1% of > 32 000 childhood cancer survivors. Therapies for hepatic cancer, Hodgkin lymphoma and leukaemia were related to the highest overall risks for CVD, with HF [relative risk 5.2 [95% confidence interval (CI) 4.5–5.9]] as the most common, followed by valvular dysfunction [relative risk 4.6 (95% CI 3.8–5.5)] and cerebrovascular diseases [relative risk 3.7 (95% CI 3.4–4.1)]. Compared with a control group, the risk for any CVD varied considerably, with an almost 20-fold increase in young patients compared with merely 1.3 for survivors >60 years of age due to a sharp increase in the incidence of common CVD. A recently published harmonization of international guidelines recommends lifelong follow-up for survivors of childhood cancer treated with either high-dose anthracyclines, high-dose radiotherapy to the chest or both.

2.10.2 Elderly patients
Elderly patients treated with cancer therapy are the second subgroup most commonly affected by cardiotoxicity, due largely to the common prevalence of classic cardiovascular risk factors and co-morbidities. A history of HF, cardiac dysfunction, arterial hypertension, diabetes or CAD all make the cardiovascular system more vulnerable to the additional burden of chemotherapy or radiation.

2.10.3 Pregnant women
There is very little evidence regarding maternal risk of cardiotoxicity. It can be expected that cardiotoxicity can be influenced by pharmacokinetic and pharmacodynamic changes occurring during pregnancy. In a recent review, the authors mentioned decreased anthracycline plasma levels in pregnant vs. non-pregnant women. On the other hand, cardiovascular overload due to the high-output state in pregnancy may counterbalance this toxicity-limiting effect and the net result is difficult to predict. Data from a small registry and a case–control trial involving 10 pregnant women suggest that the cardiotoxicity risk in pregnancy is similar to that of an age-matched female population. However, in view of uncertainties and the limited number of pregnant women requiring chemotherapy, a strategy of monitoring, including clinical cardiac assessment and echocardiographic functional evaluation, before starting chemotherapy and re-evaluation before every dose should be considered. The scarce existing data, which are mostly in vitro and experimental, suggest low placental transfer of cancer drugs, including anthracyclines, with limited exposure of the foetus. However, it is not clear whether even small concentrations of anthracyclines affect the normal development of cardiomyocytes. The long-term case observation does not show significant long-term cardiotoxic effects in children born of mothers treated with cancer therapy during pregnancy.
3. Strategies for prevention and attenuation of cardiovascular complications of cancer therapy

3.1 Treatment options to prevent or recover from cancer therapy-induced myocardial dysfunction

3.1.1 Before cardiotoxic cancer treatment

The timing and selection of cardioprotection depends upon various clinical variables. If baseline cardiotoxicity risk is high due to pre-existing CVD, previous anthracycline-containing chemotherapy or poorly controlled cardiovascular risk factors, then a very stringent optimization of risk factor control has to be obtained and a prophylactic cardioprotective medication regimen should be considered (Table 13). Cancer patients with low baseline risk for high total cumulative anthracycline doses (>250–300 mg/m² doxorubicin or equivalent) may also be considered for prophylactic cardioprotective medication. One small study randomized adults with haematological malignancies scheduled for high-dose anthracycline chemotherapy to enalapril and carvedilol at HF therapy doses vs. normal care, starting cardiac drugs before the first cycle of chemotherapy. The decrease in LVEF observed in the control arm at the 6-month follow-up was prevented in patients receiving both cardioprotective drugs. Whether patients with a low baseline risk who are treated with anthracyclines also profit from preventive treatment with ACE inhibitors, ARBs or beta-blocker therapy remains controversial, and no recommendation can be made at this time.

In a recent prospective, placebo-controlled trial in patients with early breast cancer treated with anthracyclines, the ARB candesartan, compared with placebo or beta-blocker therapy, attenuated the decrease in LVEF but had no effect on GLS or cardiac biomarkers. In this trial, metoprolol did not prevent a chemotherapy-associated decrease in LVEF. Similarly, neither the ACE inhibitor perindopril nor the beta-blocker bisoprolol had any effect on cardiac remodelling in trastuzumab-treated patients with early breast cancer, although most of these patients were not pretreated with anthracyclines and therefore were at a lower risk of cancer treatment-associated cardiac side effects.

Cancer patients with pre-existing clinical HF or significant LV dysfunction at baseline require specialist cardiology review, preferably in a specialist cardio-oncology clinic, where available, and the risk vs. benefit regarding selection of chemotherapy options should be discussed with the oncology team. Options include selection of an alternative non-cardiotoxic chemotherapy, anthracycline preparations with lower cardiotoxicity (e.g. liposomal doxorubicin), reduced-dose schedules and/or additional cardioprotective drugs (e.g. ACE inhibitors, beta-blockers, aldosterone antagonists or dexrazoxane) (Table 13). Dexrazoxane, an intracellular iron-chelating agent, prevents the reduction in LV function caused by doxorubicin and can therefore be considered an alternative to doxorubicin in selected cases.

A Cochrane meta-analysis in adult patients with cancer treated with anthracyclines, dexrazoxane significantly reduced the risk of HF with no evidence for a difference in efficacy rate, survival or occurrence of secondary malignancies between dexrazoxane and control groups. Other meta-analyses showed no differences in secondary malignancies in children treated with dexrazoxane. Currently the European license for dexrazoxane use is only for adults with advanced or metastatic breast cancer who have received a cumulative dose of >300 mg/m² doxorubicin or >540 mg/m² epirubicin and would benefit from continued anthracycline-based therapy.

3.1.2 Patients with troponin elevation

Initiation of cardioprotection may be considered in patients with cancer who have a troponin increase during treatment with high-dose anthracycline-containing chemotherapy regimens. A clinical trial that randomized 114 patients who received high-dose chemotherapy and experienced an early (within 72 h after each cycle) increase in troponin levels to enalapril vs. placebo showed a significantly lower incidence of cardiac events, including HF and asymptomatic LV dysfunction, after a follow-up of 12 months in the group treated with enalapril.

3.1.3 Patients with asymptomatic reduction in left ventricular ejection fraction during or after cancer treatment

LVEF reduction meeting the definition of cardiotoxicity may be considered as stage B HF (i.e. patients with structural heart disease but no current or previous symptoms of HF), particularly if there is a concomitant increase in natriuretic peptide. Depending upon the magnitude of the decrease and the LVEF value, initiating one or more guideline-based HF therapies should be considered.

ACE = angiotensin converting enzyme; ACE-I = angiotensin converting enzyme inhibitor; CAD = coronary artery disease; HF = heart failure; HTN = hypertension; PAD = peripheral artery disease; RCT = randomized controlled trial.
One observational study evaluated the efficacy of enalapril and carvedilol in patients with LVEF ≤ 45% detected following high-dose anthracycline-based chemotherapy. Although there was no control group, full LVEF recovery occurred in 42% of patients treated with enalapril and carvedilol. Importantly, cardiac-specific treatment within 6 months after the end of chemotherapy increased the likelihood of LV function recovery.38 In a longer-term study, optimal HF therapy appeared to be associated with an improvement in LV dysfunction noted after chemotherapy.36

3.1.4 Patients with asymptomatic reduction in global longitudinal strain during chemotherapy
Currently there is no evidence to guide specific cardioprotection if early signs of subclinical myocardial dysfunction are detected during echocardiography-based GLS surveillance.85,90,250 GLS may be a more sensitive tool to detect early cardiotoxicity, but based on currently available evidence, cancer treatment should not be stopped, interrupted or reduced in dose based on a new GLS reduction alone.

3.1.5 Patients with heart failure during and following cancer treatment
Cancer patients presenting with clinical HF during or following cancer treatment should be treated according to current ESC guidelines for HF.176,251 When presenting during chemotherapy, referral to a cardio-oncology specialist service is preferable, and close liaison with the oncology team is required to determine the necessity and duration of any interruption of cancer treatment, with interruption of cancer treatment recommended until the patient is clinically stable. Risk vs. benefit of further treatment with the previous regimen will depend upon several clinical factors, including the severity of LV dysfunction, clinical HF status, cancer prognosis and efficacy of the cancer therapy.

If rechallenge with a drug having previously generated cardiotoxicity is planned, continuation with cardioprotective drug therapy such as ACE inhibitors and beta-blockers is strongly recommended.36,230 Other potential options include the selection of preparations with a potentially less cardiotoxic profile (e.g. liposomal doxorubicin251–253) or possibly other less cardiotoxic drugs (e.g. dexrazoxane) when indicated (see section 3.1.1).240,254

3.1.6 Non-pharmacological interventions with a cardioprotective effect in patients with cancer
Positive health-promoting behaviour, including lifestyle factors (healthy diet, smoking cessation, regular exercise, weight control) should be strongly advised. In particular, aerobic exercise is considered a promising non-pharmacological strategy to prevent and/or treat chemotherapy-induced cardiotoxicity. Walking and cycling activities, even at significant levels of physical exercise, have been tested, and the benefit was greater when the exercise was more intensive, but not until exhaustion, which should be strongly discouraged.255,256

Patients receiving cancer treatment often have multiple physical and psychological adverse effects. A multidisciplinary approach is essential for long-term management of patients with cancer.257 A review of 56 trials involving 4826 participants showed an improvement in quality of life and physical ability during and after an exercise training programme (Table 14).258

3.2 Prevention of thromboembolic events
Chemotherapy increases the risk of VTE, a common cause of death in ambulatory patients. Currently, primary prevention, mainly using LMWH, should be proposed in high-risk ambulatory patients receiving chemotherapy (with multiple myeloma receiving anti-angiogenic agents or locally advanced or metastatic pancreatic or lung cancers) who do not have excessive bleeding risk.259–261

In patients hospitalized for cancer, several guidelines advocate the use of thromboprophylaxis, although a recent meta-analysis of subgroups of trials including patients with cancer hospitalized for medical conditions failed to find evidence of any global benefit or risk of primary thromboprophylaxis.262 Studies are under way to validate thromboprophylaxis based on risk factors and biomarkers. Meanwhile, it is reasonable to consider thromboprophylaxis with LMWH based on individual benefit–risk assessments.

For patients with central venous catheters, there is a reduction in symptomatic deep vein thrombosis with the use of heparin and of asymptomatic deep vein thrombosis with VKA compared with no anticoagulation. However, heparins are associated with a higher risk of thrombocytopenia and asymptomatic deep vein thrombosis compared with VKA, and therefore treatment decisions should be individualized.263

3.3 Strategies for attenuation of complications related to use of specific agents

3.3.1 Anthracyclines
Several strategies can be used to prevent the LV dysfunction and HF induced by anthracyclines while maintaining antineoplastic efficacy, including reduction in the cumulative dose; use of continuous infusions (up to 48–96 h) to decrease peak plasma levels in adult patients264–266; use of analogues (epirubicin, plynaxtrone)267 or liposomal formulations, which are thought to have a lower risk of cardiotoxicity and provide comparable antitumour efficacy or use of dexrazoxane as a cardioprotectant.255,268–272 When there is evidence of equal efficacy or superiority of non-anthracycline regimens, they should be considered, particularly in patients with established cardiovascular risk factors or previous exposure to anthracyclines.273
Taxanes reduce doxorubicin elimination, resulting in higher plasma levels, and promote its myocardial metabolism into more toxic metabolites. Paclitaxel used in combination with anthracyclines enhances their cardiotoxicity. In this setting, paclitaxel is more cardiotoxic than docetaxel. Thus it is recommended to administer anthracyclines before paclitaxel, separate the infusions and/or limit the cumulative doxorubicin dose to 360 mg/m². As indicated above, the role of cardiac medications (ACE inhibitors, ARBs and beta-blockers) for the prevention of anthracycline-associated cardiac side effects in patients with normal cardiac function and low risk before starting cancer treatment remains controversial, and more data are needed.

### 3.3.2 HER2 targeted therapy

Co-administration of anthracyclines and trastuzumab markedly increases the incidence of HF, but cardiotoxicity can be reduced significantly by introducing a drug-free interval between the two agents. In patients with metastatic disease who developed HF, an association was observed between treatment with ACE inhibitors and beta-blockers and LVEF recovery at 12 months, and a further rechallenge with trastuzumab did not necessarily lead to redevelopment of HF. Additionally, in patients with breast cancer and normal LVEF before receiving trastuzumab and anthracycline therapy, continuous use of beta-blockers reduces the incidence of HF. Whether this finding is also true for patients who were treated predominately with non-anthracyclines before trastuzumab remains controversial and no recommendation can be made. The National Cancer Research Institute recommends that if LVEF decreases to < 45% or > 10 percentage points from baseline to a value between 45% and 49%, trastuzumab should be interrupted and ACE inhibitors should be started; trastuzumab may be reinitiated if the LVEF is restored to > 49%. If LVEF decreases below 50% but > 44%, trastuzumab may be continued but an ACE inhibitor should be initiated. If the decrease occurs despite ACE inhibitor therapy, the patient should be referred to a cardiologist, and preferably a cardio-oncology service where available. In selected cases it may be preferable to choose a beta-blocker rather than an ACE inhibitor, depending on co-morbidities. The reversibility of LV dysfunction and the opportunity to resume administration of trastuzumab after improvement in HF needs to be evaluated in a prompt manner, and management should be individualized considering the each patient’s characteristics. Ongoing trials are evaluating the prophylactic role of candesartan (NCT00459771), lisinopril–carvedilol (NCT01009918) and perindopril–bisoprolol (NCT01016886) combinations in reducing trastuzumab-induced cardiotoxicity.

The European Society for Medical Oncology guideline for prevention of trastuzumab-induced cardiotoxicity recommends a delay between completion of an anthracycline-based regimen and initiation of trastuzumab, careful assessment of cardiac function before starting and during follow-up and prophylaxis with ACE inhibitors for the control of hypertension or new-onset LV dysfunction.

Regular aerobic exercise seems a promising strategy to attenuate doxorubicin-induced LV dysfunction, but not trastuzumab-induced cardiotoxicity.

### 3.3.3 Pyrimidine analogues

In cancer patients with pre-existing CAD receiving drugs that may produce myocardial ischaemia, aggressive control of CAD risk factors (smoking, hypertension, diabetes, hyperlipidaemia) followed by pharmacological treatment according to ESC guidelines should precede the administration of these drugs. Patients treated with pyrimidine analogues frequently present angina pectoris, ischaemia-related ECG abnormalities, arrhythmias and myocardial infarction, even in patients with normal coronary arteries. Risk markedly increases in patients with a history of CAD, and since prophylactic administration of nitrates and/or calcium channel blockers may not be effective, pyrimidine analogues should be discouraged in these patients. However, if an alternative therapy is not available, close monitoring of the patient is advised.

### 3.3.4 Vascular endothelial growth factor signalling pathway inhibitors

Careful assessment of cardiovascular risk factors at baseline, close blood pressure monitoring and discontinuation of drugs known to raise blood pressure are essential to ensure prompt and aggressive management of hypertension in patients treated with VEGF signalling pathway inhibitors. Pharmacological strategies have been reviewed (see section 2.5).

### 3.3.5 Radiotherapy

Heart-sparing radiotherapy techniques should be oriented towards lowering the dose of radiation and the cardiac volume exposed from regional radiotherapy to involved field or involved node radiotherapy (e.g. in Hodgkin lymphoma). These results may be reached using modern techniques based on 3D treatment planning with a dose–volume histogram and virtual simulation programmes. Using CT or magnetic resonance imaging, powerful software systems are able to precisely delineate the contours of the cancer and to guide delivery of radiation. To reduce the cardiac radiation dose during radiotherapy, the following techniques and strategies have been described:

- The deep inspiration breath-hold technique, or respiratory gating, allowing shielding of the heart from tangential fields and reduction of radiation to organs at risk without compromising clinical target volume.
- Multiple or rotational sources of radiation beams (photons/electrons).
- Linear accelerator photons allowing treatment of patients with equal weighting of anterior and posterior portals, with subcarinal block and the shrinking field technique.
- Intensity-modulated radiation beams using multileaf collimators are superior to partial shielding.
- Reporting and minimization of radiation doses received by normal tissue.
- Tracking systems, consisting of a small linear particle accelerator mounted on a general purpose industrial robot with a robotic arm, allowing the energy to be directed at any part of the body from any location. The robotic mounting through a complex imaging system and software allows very fast repositioning of the source and adaptation of radiation delivery, according to patient movement and cancer modification, with an accuracy of 0.5 mm. This method of radiotherapy treatment resembles a surgical treatment and is also called ‘ radiosurgery.’
- Planning of radiotherapy to minimize the maximal distance between the anterior cardiac contour and posterior tangential field edges.
Supine voluntary deep inspiration breath-hold techniques reduced
whole heart and left anterior descending coronary artery radiation
doses for some patients with left-sided breast cancer.296
Despite adoption of these measures, irradiation of the heart is
unavoidable when the target volume is close, such as in left breast
cancer and some cases of Hodgkin lymphoma.

4. Long-term surveillance programmes for cancer survivors
The population of patients surviving for long periods after the diag-
nosis and treatment of cancer has substantially increased over the
past decade.297,298 It is imperative to raise awareness of possible car-
diac disease among cancer survivors as well as to provide appropriate
follow-up of such patients in clinical practice. Patients should be
informed of their increased risk of CVD at the outset of their
chemotherapy and should be advised and supported to make appro-
priate lifestyle modifications. They should also be instructed to
promptly report early signs and symptoms of CVD.

Depending on the cancer and the treatment, a range of cardiovas-
cular complications can arise. For the purposes of clarity, only the
most common will be discussed here, but a strategy to screen for
important cardiovascular conditions will be outlined. In general,
the cardiovascular concerns can be summarized in categories
related to myocardial dysfunction, vascular disease and VHD.

4.1 Myocardial dysfunction
Both paediatric and adult survivors of anthracycline-based chemo-
therapy have a lifelong risk for the development of LV dysfunction
and HF.10,34,299 The time lapse between treatment and the develop-
ment of HF can be very long (>10 years).300 Thus, even in asym-
tomatic patients treated with cardiotoxic therapy, particularly
anthracyclines, LV dysfunction and HF can potentially occur. Period-
ic screening with cardiac imaging and biomarkers, such as BNP,
should be considered in survivors, particularly those treated with
high cumulative doses or who demonstrated reversible LV dysfunc-
tion during cancer treatment.301,302 Any symptom suggestive of HF
should be similarly investigated, as many intercurrent illnesses may
unmask reduced cardiac reserve in patients with previous anthracy-
cline exposure. Early discontinuation of cardioprotective HF ther-
apy is not recommended. Although clinical trial data are still lack-
ing, the recommendation of this Task Force is to continue HF
therapy indefinitely unless normal systolic LV function remains
stable after cessation of HF therapy and no further cancer therapy
is planned. Since trastuzumab-induced cardiac dysfunction is fre-
cently reversible, cessation of HF treatment after normalization
of LVEF may be considered for these patients.3

4.2 Vascular disease
Evaluation for CAD, ischaemia and vascular disease is recom-
mented in patients with a history of mediastinal radiation, even if
asymptomatic, starting 5 years post-treatment and then at least
every 5 years thereafter.302,303 At least one major study suggested
that important cardiac disease is silent in a high percentage of pa-
tients with cancer who received mediastinal radiation, and screening
for ischaemic heart disease is a recommended practice.304 Vascular
damage may be present in areas distant to the radiation field when
patients are also given chemotherapy in addition to radiotherapy.305
Owing to the increased risk of stroke in patients with previous neck
irradiation, ultrasound scanning of carotid arteries to rule out
the presence of subclinical atherosclerosis could be included for a
comprehensive cerebrovascular risk assessment.

4.3 Valvular disease
Radiation-induced VHD is an increasingly recognized entity occur-
ing late after mediastinal radiotherapy, with a median time to diag-
nosis of 22 years.306 A minority of patients have completely normal
functioning aortic valves at the 20-year follow-up. Childhood cancer
survivors have a higher than expected incidence of tricuspid regur-
gitation, and the explanation remains to be determined.307 Affected
survivors are often no longer under the care of a treating cancer
specialist at the time of VHD diagnosis and, strikingly, the diagnosis
of cancer or history of radiation therapy is often not mentioned in
the patients’ current medical records.308 The European Association
of Cardiovascular Imaging and the American Society of Echocardi-
ography (EACVI/ASE) recommend a focused yearly history and
physical examination with echocardiography in symptomatic pa-
tients.308 For asymptomatic patients, the EACVI/ASE consensus
document309 recommends a screening transthoracic echocardi-
ogram at 10 years post-radiation and serial exams every 5 years there-
after. Transoesophageal echocardiography adds important
information, especially when significant calcification or fibrosis is
present and limits transthoracic image quality. In addition, 3D echo-
cardiography may be helpful in the evaluation of mitral valve morph-
ology. CMR may also be useful in those with suboptimal
echocardiography or discrepant results.310

5. Future perspectives and research directions
Cardio-oncology is a field with many unmet needs and gaps in
knowledge to guide best practice.311 The barriers separating oncology
and cardiology are dissolving rapidly from both disciplines, because for
patients with cancer, cure is not enough. The number of long-term
survivors is increasing, with the focus on cardiac health becoming a pri-
ority. A close collaboration between oncologists and cardiologists is
already perceptible in several centres where a cardio-oncology team
is clearly identifiable. Some centres, called cardio-oncology centres,
have developed a well-structured service that includes several health-
care professionals (nurses, doctors, cardiologists, imaging specialists,
oncologists, etc.) with expertise in this field.

Cardiologists have particular challenges and responsibilities in this
emerging interdisciplinary alliance. These include a careful initial
evaluation before starting potentially cardiotoxic chemotherapy
and optimal control of pre-existing cardiovascular risk factors,
followed by ongoing cardiac safety monitoring for early signs of car-
diovascular toxicity and timely implementation of preventive or
therapeutic measures.312,313 All of this coordinated activity is crucial
to reduce both the burden of potential cardiovascular complica-
tions as well as the number of patients disqualified from specific
cancer treatment because of emergent CVD.311,312 Oncologists
and haematologists are faced with uncertainty over whether to
disqualify a patient from treatment due to baseline CVD, although cancer therapy might be lifesaving, or administer treatment and wait until signs of cardiac injury. The latter strategy requires reliable and sensitive methods for the early detection of cardiac toxicity, which still remain to be defined, and effective strategies to mitigate potential cardiac injury. Indeed, there is an urgent need for more validated data to optimally manage and support patients at risk of cardiovascular complications and exacerbation of cardiac disease during the course of cancer treatment.

One of the most important unresolved issues is the choice between a primary vs. secondary prevention strategy. It is still unclear whether primary prevention is only relevant in patients at highest cardiovascular risk or when using therapy with a high cardiotoxic potential. Data on the prevalence and severity of clinically relevant cardiotoxicity are generally disease and treatment specific and are lacking for many clinical situations. For instance, a young patient with breast cancer without cardiovascular risk factors is unlikely to benefit from primary prevention during most breast cancer treatment, whereas an elderly patient with lymphoma would likely benefit from cardioprotection during anthracycline therapy. Therefore, it is also unclear whether a primary prevention strategy is justified and cost effective in low-risk populations. The existing evidence supporting cardiovascular preventive strategies in cardio-oncology is only suggestive and requires further validation. With the encouraging trend of the steadily improving survival rate for childhood cancer survivors, there is an increasing responsibility to identify patients with adverse health outcomes related to past cancer treatments.

While primary prevention of cardiotoxicity is still in the research domain, secondary prevention has already entered clinical practice guidelines despite persistent unresolved questions. There is some evidence that good control of common cardiovascular risk factors at initiation of chemotherapy mitigates the cardiovascular consequences of cancer treatment in patients with a history of hypertension, diabetes and HF. Prospectively validated criteria of early cardiotoxicity, which would be representative of late morbidity and mortality, are needed. The sensitivity of the current approach based on serial assessment of LVEF is insufficient. The combined biomarker and imaging approach also suffers from a set of limitations. Several circulating biomarkers (troponin I and BNP or NT-proBNP) have been identified as useful for the early detection of myocardial dysfunction and overt HF related to cancer therapies. However, conclusive data are needed to establish whether biomarkers reliably predict clinically relevant late consequences of cancer treatment. The effect of interrupting cancer therapy remains to be determined, but should not be taken lightly, as there are examples in general of interruptions or incomplete treatment courses having an adverse effect on optimal cancer treatment outcomes.

All of these challenges call for further concerted research. At this stage, large, properly designed comprehensive trials could provide answers to several of the above questions. As an example, primary prevention could be compared with careful observation in which secondary prevention measures would be triggered by a reduction in LVEF or a significant increase in a cardiac biomarker. Concomitant biobanking of blood samples, not only for testing cardiac biomarker levels, but also for genetic and epigenetic characterization of patients, could provide future means to differentiate patients who are particularly susceptible or resistant to cardiotoxicity from a specific cancer treatment.

A strategy that could better stratify risk would identify patients in which primary prevention or secondary prevention would be the most beneficial. To succeed, there is a need for

- refining the predisposing factors for the development of CVD related to cancer treatment,
- evaluating the rate of subclinical LV dysfunction and its transition to overt HF,
- defining the most reliable cardiac monitoring approach and
- determining the clinical effect and outcome (in terms of morbidity and mortality) after cancer therapy.

All of these actions are in concert with the aims of the recently launched EACVI/Heart Failure Association Cardiac Oncology Toxicity (COT) registry.

Comparing clinically relevant outcomes with genetic, epigenetic, biomarker and imaging characteristics assessed at baseline and during active cancer treatment could provide data that would allow the construction of true evidence-based strategies and open a new era in cardio-oncology. The medical, social, ethical and economic relevance of such a trial would be convincing for public and European granting agencies. One of the important goals of this position paper is to catalyse such initiatives. The alliance between oncologists and cardiologists should also act as a lobby for introducing the analysis of early and late cardiovascular side effects of new cancer drugs into clinical trials, especially for patients with childhood cancer who are at increased risk of chronic medical problems concerning the vascular system. Innovative pharmaceutical companies should recognize that the time when cardiovascular safety will determine the choice of personalized cancer treatment, with all the economic and marketing implications of such an approach, is just around the corner.
